## Container with at least one electrode

5 The invention concerns a container for receiving an aqueous solution, and in particular cells, derivatives of cells, subcellular particles and/or vesicles, which is formed at least partially by an outer limit forming an inner chamber for receiving said solution, and which comprises at least one area which acts as an electrode when an electric voltage is applied and a subsequent discharge occurs.

10

### Background of the Invention

Transferring biologically active molecules, such as, for example, DNAs, RNAs or proteins, into living cells is an important tool for analysis of biological functions of these molecules. Electroporation is a preferred method for 15 transferring foreign molecules into the cells, which in contrast to chemical methods causes less undesirable changes of the biological structure and function of the target cell. During electroporation the foreign molecules are introduced into the cells from an aqueous solution, preferably a buffer solution adapted to the cells or a cell culture medium, by a short-time current flow, i.e. 20 the pulse of a discharging capacitor, whereby the cell membrane is made permeable for the foreign molecules by effect of the short electric pulses. Solution and cell suspension, respectively, are usually provided in a so-called cuvette, i.e. a small container which is open at the top and which comprises two 25 oppositely and parallel arranged electrodes disposed in the sidewalls near the bottom and serving for the application of electric voltage. Through the temporarily emerging "pores" in the cell membrane the biologically active molecules initially reach the cytoplasm where they eventually already exert their function to be analysed. At certain conditions the molecules subsequently also 30 enter the nucleus of the cell. Particularly with the introduction of DNA into animal cells, the so-called transfection, specific problems often arise during electroporation because of the fragility of the cells since the efficiency of

transfection is affected by the survival rate of the cells as an important parameter.

Due to the temporarily applied intensive electric field, i.e. a short pulse with high  
5 current density, cells, derivatives of cells, subcellular particles and/or vesicles  
can also be fused. During this so-called electrofusion at first, for instance, the  
membranes of the cells are brought in close contact by an inhomogenous  
alternating electric field. The subsequent application of an electric field pulse  
10 leads to an interaction of parts of the membranes, which finally leads to cell  
fusion. Comparable devices such as the ones used for electroporation can be  
used for electrofusion as well.

### State of the Art

15 Containers as mentioned above are known and primarily used for  
electroporation or electrofusion in the form of cuvettes having inserted  
electrodes made of metal. Containers used for this purpose are mostly small  
vessels which are closed at the bottom and open at the top and whose inner  
space is build by two pairs of parallel and oppositely arranged sidewalls. The  
20 inner space serves for receiving of the cell suspension, i.e. usually an aqueous  
buffer solution or a cell culture medium, in which the cells to be treated are  
suspended. Such cuvettes mostly comprise a pair of electrodes for application  
of an electric voltage disposed near the bottom of a pair of oppositely arranged  
sidewalls. During an electric discharge an electric current flows through the cell  
25 suspension between both electrodes, which enables an introduction of nucleic  
acids or other molecules into the cells or, depending on the selected conditions,  
leads to fusion of cells. The electrodes are mostly made of metal, wherein  
aluminium is frequently used. But it is an disadvantage of these known,  
commercially available cuvettes that metal ions are emitted into the buffer  
30 solution during the electric discharge, which can cause an undesirable  
stimulation of the cells at lower concentrations or, at higher concentrations, act  
toxic on the cells. For instance, using cuvettes made of aluminium a negative  
effect due to the release of  $Al^{3+}$  ions could be demonstrated (Loomis-Husselbee

et al., Biochem J 1991, 277 (Pt 3), 883 – 885). Furthermore, using cuvettes having electrodes made of metal generation of undesirable precipitates may occur, which are also generated due to the release of metal ions from the electrodes. The precipitates may be metal hydroxides or complexes of metal ions with biological macromolecules of the buffer solution (Stapulionis, Bioelectrochem Bioenerg 1999, 48(1), 249 – 254). Finally, it is another disadvantage of cuvettes made of aluminium that the resistance of the cuvettes decreases during discharge, presumably because a layer of oxidized aluminium having a higher resistance is released from the electrode by the current flow. Additionally, cuvettes having electrodes made of metal are difficult to produce and very expensive.

US 6,001,617 discloses a device for cultivation of cells, which can be used for electroporation as well as for electrofusion of cells. The device consists of a round container having an optically transparent bottom on which a layer of cells can adhere and grow. The bottom of the container may consist of an optically transparent, non-conductive material being coated with an electrically conductive material, or can be completely made of an optically transparent and electroconductive material. The electroconductive bottom is contacted via a band-like electrode made of metal and being circumferentially disposed in the wall area. To act as counter electrode a likewise circular band is provided. It is one drawback of this known device that it is primarily provided and suitable for electroporation of adhering cells. Using this device for transfection of suspended cells is limited and merely possible if low efficiency is accepted. Due to the ring-like circular contacting of the bottom electrode and the counter electrode being likewise circumferentially disposed in the wall area a homogenous electric field cannot be generated so that equal transfection of all cells cannot be achieved. This effect is increased by the fact that the intrinsically conductive plastics used have a higher resistance as they are provided as thin coating. Thus, the cells adhering to the bottom in the centre of the surface can only be transfected with very low efficiency. Furthermore, because of the sophisticated construction and the fact that the intrinsically

conductive plastics used are not mouldable, the production of the known container is very expensive.

#### Description of the Invention

5

It is thus the object of the invention to create a container as mentioned above in order to overcome the existing deficiencies, which can be produced easily and cost-effectively, and which allows an efficient treatment of cells, derivatives of cells, subcellular particles and/or vesicles using electric current.

10

According to the invention the object is solved in that at least one electrode is made of a conductive synthetic material at least based on a plastic material which is doped with at least one conductive substance. To avoid the release of metal ions a conductive synthetic material being made of doped plastic is used.

15

Thus, toxic effects, for instance on living cells, such as during the release of  $Al^{3+}$  ions can be avoided. Medical compatibility of the generating products can also be enhanced this way so that, for example, the possible use of transfected primary cells for ex vivo gene therapy is supported. As a result of doping the plastics with conductive substances, a current flow between both electrodes could be achieved during discharge, which is equal to the current flow using commonly used cuvettes having metal electrodes. Surprisingly, it has been determined that using the used doped plastic material with electroporation better results in respect of the transfection efficiencies can be achieved if compared to the use of, for instance, cuvettes having electrodes made of aluminium. By avoiding the toxic effects caused by the release of metal ions the ratio of transfection efficiency to cell mortality is significantly increased. It is a further advantage of the container according to the invention that no precipitate is created in the solution during electric discharge, which could adhere to the cells and impair further analysis and use of transfected cells, respectively.

30

Obviously, it is yet a further advantage of the container according to the invention that the buffer solution has less effect on the doped plastic electrodes used. It was actually determined that in the cause of discharge very high resistance is generated at the surface of the electrode, which, at a given start

current, causes a drastical decrease of current flow, if buffers containing phosphate but no chloride are used with cuvettes made of aluminium. Surprisingly, this can be avoided by using the container and electrodes according to the invention, respectively. The containers according to the invention are thus merely affected by the conductivity of the solution but not negatively affected by the buffers used. The containers according to the invention can be injection-moulded in one mould using two-component injection moulding because doped synthetic material, in contrast to intrinsically conductive plastic, is injection-mouldable. Thus, the container according to the invention can be produced in an easy and cost effective manner. The doped plastic material may have a density, for example, between 1.3 and 1.5 g/cm<sup>3</sup>, preferably a density of 1.37 or 1.54 g/cm<sup>3</sup>, and a melting temperature of 230 to 310 °C. Preferably, the doped plastic material has a specific forward resistance of 2 Ohm x cm or less, and a specific input resistance of 10<sup>4</sup> Ohm or less.

In respect of the conductivity of the synthetic material it turned out to be particularly advantageous if the dope consists of carbon fibers, graphite, soot, carbon nanotubes and/or an intrinsically conductive synthetic material. The overall concentration of the dope in the plastic material should be in the range between 10 and 80 % w/w. The conductivity of the synthetic material is not sufficient below a percentage of 10 %, while the possibility to injection-mould the synthetic material is extremely reduced above a percentage of 80 %. Using the container according to the invention with electroporation or electrofusion of cells, derivatives of cells, subcellular particles and/or vesicles it has been shown that it is particularly advantageous in respect of conductivity that the overall concentration of the dope is 20 – 60 % w/w, more preferred 40 – 60 % w/w, particularly preferred 50 – 60 % w/w, in particular 55 – 60 % w/w.

Several applications, in particular transfection of DNA into the nucleus of primary cells, need particularly high electric currents and field strengths, respectively, in the solution to achieve sufficiently high efficiencies. In these cases it is advantageous if the overall concentration of the dope in the plastic material is between 40 and 80 % w/w. This ensures a high conductivity of the

electrodes so that flow of sufficiently high currents through the solution and the inner space of the container, respectively, is possible. In an advantageous embodiment of the invention the concentration of the dope may be in the range of 50 – 80 % w/w, preferably 60 – 80 % w/w, more preferred 70 – 80 % w/w, in particular 74 – 76 % w/w, depending on the application and the type of the cells to be treated. A sufficient injection-mouldability of the material is ensured in this respect even if the dope has high concentrations up to 80 % w/w. In this respect, the use of particular mixtures of dopes, e.g. carbon fibers and graphite, may have a positive influence on mouldability.

10

In respect of the injection-mouldability of the synthetic material it turned out to be particularly advantageous if the plastic material is polycarbonate, polyetheretherketone, polypropylene, polyamide, polyphenylsulfide or a mixture of these polymers, or at least based on one or several of these polymers, and/or wherein said plastic material is an intrinsically conductive synthetic material. In this respect, the use of polyamide 66 or polyamide 6 is particularly advantageous.

If the synthetic material itself is doped with an intrinsically conductive synthetic material, an advantageous embodiment of the invention is provided, wherein the intrinsically conductive synthetic material is polyaniline, polyacetylene, poly-para-phenylene, poly-para-phenylsulfide, polypyrroles, polythiophene, polypropylene or the like, or at least based on one or several of these polymers.

In another advantageous embodiment of the invention it is provided that the outer limit is made of synthetic material, preferably transparent plastic material, because it is thus possible to produce the entire container using injection moulding methods. It may be advantageous in this respect if the outer limit is made of the same plastic material as the plastic material on which the at least one electrode is based. In this embodiment there may be benefits with the processing of the synthetic material using two-component injection moulding. Thereby, on the one hand the production is simplified and on the other hand the

production costs are reduced. However, for special applications, the outer limit may consist of other material as well.

5 In a particularly advantageous embodiment of the invention it is provided that the at least one electrode is integrated into said outer limit so that the container can be injection-moulded in one mould.

10 In a preferred embodiment of the invention it is provided that the container comprises at least two electrodes being made of the same material. Most applications use containers and cuvettes, respectively, which have two oppositely arranged, parallel electrodes consisting of the same material. These two electrodes are contacted in a suitable manner and thereby connected to a voltage source adapted to the respective requirements. However, in special cases it may also be beneficial if at least two electrodes are made of different materials. In these cases, the anode or the cathode may consist of the doped synthetic material while the respective counter electrode may consist of another material, e.g. stainless steel or an intrinsically conductive synthetic material.

20 The containers comprising electrodes made of a conductive synthetic material according to any one of the claims 12 to 18 proved to be particularly advantageous for transfection of living cells. These containers have a high conductivity combined with electrode material which is easily processable.

25 In an alternative embodiment of the invention it is provided that the outer limit comprises at least one opening for supplying the solution and at least one opening for draining off the solution. The container according to the invention can thereby also be used as flow-through container with which the solution flows through the inner chamber continuously or discontinuously.

30 The containers according to the invention are advantageously suitable in the form of container arrangements comprising at least two, preferably 6, 12, 24, 48, 96 or more, containers being joined to build one unit, i.e. so-called "multi-wells".

It is a particular advantage of the invention that the containers or container arrangements according to the invention can be produced using a method, wherein the container or the container arrangement is produced by two-component injection moulding, wherein at first the outer limit is injection-moulded leaving one recessed window and the conductive synthetic material being made of doped plastic is subsequently injection-moulded into this at least one window, or wherein at first the at least one electrode is injection-moulded of the doped plastic material and the outer limit is subsequently injection-moulded around the at least one electrode. Contrary to the production of containers or cuvettes with electrodes consisting of metal, with which the electrodes have to be manually or automatically placed into the moulded frame or mould before or after moulding of the container, the invention provides a very easy and cost-effective method of production. The containers or container arrangements according to the invention can be injection-moulded in one mould in a two-step method so that the costs of their production are significantly lower as the usual costs for the production of electroporation or elektrofusion cuvettes.

Advantageously, the containers or container arrangements according to the invention are particularly suitable for use in methods for treatment of cells, derivatives of cells, subcellular particles and/or vesicles by means of electric current, in particular for electroporation or electrofusion, wherein the cells, derivatives of cells, subcellular particles and/or vesicles are transferred into an inner chamber of at least one container or at least one container of a container arrangement, wherein said container comprises at least one electrode being made of a doped synthetic material, and at least one further electrode, and wherein a voltage is then applied to said electrodes and a current flow is generated in the inner chamber of said container. In this method, the electric current may reach a current density up to  $120 \text{ A/cm}^2$ , preferably  $80 \text{ A/cm}^2$ , and the cells, derivatives of cells, subcellular particles and/or vesicles may be provided in suspension, or adhered or in otherwise immobilized condition.

Accordingly, beside other possible applications, the containers or container arrangements according to the invention are suitable, for instance, for

electroporation, i.e. methods for introducing biologically active molecules into living cells using electric current, wherein biologically active molecules, in particular nucleic acids, are solved in said solution, and transfer of said biologically active molecules into living cells is achieved by means of a voltage pulse having a field strength of 2 to 10 kV\*cm<sup>-1</sup> and a duration of 10 to 200 μs. Subsequently, a current flow following said voltage pulse without interruption, having a current density of 2 to 14 A\*cm<sup>-2</sup>, preferably 5 A\*cm<sup>-2</sup>, and a duration of 1 to 100 ms, preferably 50 ms, can be provided. In this method, the cells can be used, for example, in suspension or as an adhering cell layer.

10

The containers or container arrangements according to the invention are also suitable, for instance, for electrofusion, e.g. methods for fusion of cells, derivatives of cells, subcellular particles and/or vesicles using electric current, wherein the cells, derivatives of cells, subcellular particles and/or vesicles, for example, are suspended at a suitable density in an aqueous solution, said suspension is subsequently transferred into a container or container arrangement according to the invention, and finally an electric voltage is applied to the electrodes generating a current flow through the solution. Alternatively, for example, also adhering cells, derivatives of cells, subcellular particles and/or vesicles can be fused as well as, for example, adhering cells with suspended cells, derivatives of cells, subcellular particles or vesicles.

20

The invention is described below in detail with reference to the drawings.

10 of a voltage pulse.

Figure 1 shows a perspective representation of an experimental assembly 1 for demonstration of the present invention and for testing of the containers according to the invention, respectively. The experimental assembly 1 is  
15 equivalent to the construction of the containers according to the invention and comprises a spacer plate 2 and two electrodes 3, 4 being pressed against both sides of the spacer plate 2. The spacer plate 2 is a plate made of Teflon having a thickness of 2 mm, which has an U-like formed recess 5. The electrodes 3, 4 consist of a synthetic material which is doped with at least one conductive  
20 substance. The synthetic material may be, for example, polycarbonate, polyetheretherketone, polypropylene, polyamide, polyphenylensulfide or a mixture of these polymers and/or an intrinsically conductive synthetic material. The three layers which include the spacer plate 2 and both electrodes 3, 4 are pressed together at both sides like a sandwich by the copper plates 6, 7. For  
25 this purpose, the copper plates 6, 7 are moved towards the other by the threaded parts 8, 9 of a vise-like device (not shown). When the above-named layers are pressed together an inner space 10 is then formed in the range of the recess 5, which has the capacity to receive the solution and cells, respectively. In the depicted model the inner space 10 can receive a volume of 100 ml. The  
30 inner space 10 is further formed at the bottom and at both sides by the inner edges 11 of the spacer plate 2, and at the two remaining sides by the electrodes 3, 5. The copper plates 6, 7 are electrically contacted via two wires to spring contacts of a customary electroporation device, i.e. a voltage source.

The electrodes 3, 4 themselves are in direct contact to the copper plates via their entire outer surface so that the best electric contact is ensured. Thus, using the experimental assembly 1 as shown, a current flows between the electrodes 3, 4 through the inner space 10 filled with the solution and the cell suspension, respectively, if a voltage pulse is applied to the copper plates 6, 7.

Figure 2 shows the current flow of electric discharges using electrodes according to the invention, which are made of polycarbonate with 20 % carbon fibers and 15 % graphite (PC + CF + Gr), compared to the use of electrodes made of aluminium. In this approach, the current flow through two different buffer solutions was measured (Solution A: 100 mM sodiumphosphate, pH 7.1 and 25 mM potassiumchloride; solution B: 140 mM sodiumphosphate, pH 7.1). A first voltage pulse of 1000 V and 40  $\mu$ s duration was always applied followed without interruption by a second pulse having a start voltage ( $U_{\text{start}}$ ) of 90 V and a charge of 75 mC. The respective current flow of the second pulse is shown in this representation. Surprisingly, it turned out that, if the electrodes made of synthetic material according to the invention are used, a similar current flow of that scale can be achieved under the same conditions as can be achieved with the customary electrodes made of aluminium (comparisons a and c). The doped synthetic material is thus particularly suitable for conducting high current densities in a short period of time. Using a phosphate buffer without chloride (Solution B) in contrast to the use of a phosphate buffer containing chloride (Solution A) it turned out that in the course of discharge a very high resistance is increasingly generated at the surface of electrodes made of aluminium, which causes a drastic decrease of current flow at the same start current (b). This negative effect does not occur when doped synthetic material is used (d) so that, contrary to usually used cuvettes, the containers or electrodes according to the invention are also suitable for the use of phosphate buffers without chloride. Thus, using the containers according to the invention the selection of the buffer solution is not as limited as with the use of conventional containers.

Figure 3 shows a perspective representation of an experimental assembly 12 which is modified in comparison to the experimental assembly 1 according to

figure 1. The experimental assembly 1 according to figure 1 shows an arrangement where the electrodes 3, 4 are contacted by the copper plates 6, 7 using relatively high pressure on a large surface. Since contacting of the outside of electrodes, for example with a conventional electroporation apparatus, is usually not carried out with such a high pressure on such a large surface, in this experimental assembly 12 the surfaces contacting the electrodes are designed smaller. Thus, this assembly is more equivalent to a contacting by spring contacts and hence to the actual conditions in reality. For this purpose, round and v-like bended copper wires 13, 14 having a diameter of about 1.5 mm were placed between the electrodes 3, 4 and the respective adjacently arranged copper plates 6, 7. In the following, figure 4 shows a comparison of the current flows if the experimental assemblies according to figure 1 and 3 are used.

Figure 4 shows the current flow of electric discharges using electrodes made of polycarbonate including 20 % carbon fibers for the experimental assembly 1 according to figure 1 (a) as well as for the experimental assembly 12 according to figure 3 (b). The current flows of the second pulse are always shown (1. Pulse: 100 V, 40  $\mu$ s; 2. Pulse:  $U_{\text{start}} = 90$  V, 75 mC). The constant result shows that obviously the electric potential is steadily distributed on the inside of the electrodes and the contacting surface is thus not the limiting factor in respect of conductivity.

Figure 5 shows diagrams of a flow-cytometric analysis of transfected CHO cells. Transfection experiments are conducted using the experimental arrangement described in figure 1 in order to biologically determine the functionality of the containers according to the invention. For this purpose, CHO cells were suspended in 100  $\mu$ l of an appropriate buffer solution, for example PBS (phosphate-buffered saline), adding 5  $\mu$ g of the expression plasmid pH-2K<sup>k</sup> (DNA vector which codes for the heavy chain of a mouse MHC class I protein), and then transferred into the inner space of the experimental assembly. Electroporation of the cells is then carried out by application of two pulses (1. Pulse: 1000 V, 100  $\mu$ s; 2. Pulse  $U_{\text{start}} = 108$  V, 100 mC). The cell suspension was subsequently removed, transferred into an appropriate medium, for

example RPMI medium, and harvested after 20 hours incubation at 37 °C and 5 % CO<sub>2</sub>. Adhering CHO cells were washed with PBS and detached using 0.1 % trypsin + 2 mM ethylenediaminetetraacetate in PBS. The expression of H-2K<sup>k</sup> was revealed using antibody staining (1:100 anti-H-2K<sup>k</sup> (Becton Dickinson) + 1:50 beriglobine (Aventis Behring) in PBS, 10 minutes at room temperature). The dead cells were stained with 0.25 µg/ml propidiumjodide. The analysis was carried out in a flow-cytometer (FACScalibur, Becton Dickinson). Diagrams a) and b) show that using electrodes with doped synthetic material (PC/CF/Gr = polycarbonate + 20 % carbon fibers + 15 % graphite and PEEK-CF = polyetheretherketone + 40 % carbon fibers) at least similar results can be achieved in respect of transfection efficiency compared to the use of electrodes made of aluminium. Due to the significantly lower mortality rates if electrodes according to the invention are used, a significant advantage in comparison to the use of conventional electrodes is achieved because of the better ratio of transfection efficiency to mortality.

Figure 6 shows diagrams of a flow-cytometric analysis of transfected HL60 cells (human lymphoma cells). Realisation and conditions of this approach correspond to that described in figure 5 with the exception that during electroporation the voltage pulses were modified (here: 1. Pulse: 1000 V, 70 µs; 2. Pulse: U<sub>start</sub> = 81 V, 22 mC). In this approach, results could be achieved using electrodes made of doped synthetic material, which are at least similar to those if electrodes made of aluminium are used.

Figure 7 shows diagrams of a flow-cytometric analysis of transfected Jurkat cells (human T-cell line) using electrodes according to the invention made of polyamide 66 which was doped with 30 % carbon fibers. Electroporation was carried out in 100 µl RPMI medium without phenolred with 5 µg of the plasmid pEGFP-C1 by a pulse of 150 V and 5 µs followed by a pulse having a start voltage of 108 V and a charge of 80 mC. The analysis was carried out after 4 hours. Also in this example, transfection efficiency as well as survival rate could be significantly increased by the use of containers or electrodes made of doped synthetic material according to the invention in comparison to conventional

electrodes made of aluminium. Thus, the results depicted in figures 5 – 7 clearly prove that, compared to conventional cuvettes, in electroporation the transfection efficiencies can be significantly increased and the mortality rate can be significantly decreased if the containers according to the invention are used.

5 This can be primarily explained by the fact that, surprisingly, similar current flows can be ensured using electrodes according to the invention while the known drawbacks due to the release of metal ions from the electrodes and hence toxic effects on the cells can be avoided.

10 Figure 8 shows diagrams of a flow-cytometric analysis of transfected HUVEC cells (human umbilical cord vein endothelial cells) using electrodes made of polyphenylensulfide with 40 % carbon fibers according to the invention compared to conventional electrodes made of aluminium. Transfection was performed in a cell specific medium including 5 µg/100 µl plasmid DNA, wherein  
15 in this approach various voltage pulses were applied for compensation of the somewhat lower conductivity of the doped synthetic material (Pulse for PPS/CF: 1000 V, 100 µs; Pulse for aluminium: 500 V, 100 µs). After 60 hours incubation the cells were flow-cytometrically tested for expression of a fluorescent protein. Dead cells were stained with 0.25 µg/ml propidiumjodide in this approach as  
20 well. The results show that the containers according to the invention are generally also suitable for primary human cells. Also in this approach, the ratio of transfection efficiency to mortality rate is better than with the use of conventional electrodes made of aluminium. This effect can be further enhanced by compensation of the effectively higher resistance of the doped  
25 synthetic material by increasing the applied voltage. By this measure, the electric conditions within the cell suspension can be adapted if electrodes made of doped synthetic material are used and the transfection efficiency can be further increased.

30 Figure 9 shows micrographs of CHO cultures always two days after electroporation using electrodes made of aluminium (a) and electrodes made of polyphenylensulfide including 40 % carbon fibers (b). Also in this approach, the somewhat lower conductivity of electrodes made of doped synthetic material

was compensated by an increase of the first and second voltage pulses (PPS/CF: 1000 V, 100  $\mu$ s and  $U_{\text{start}} = 108$  V, 100 mC; Aluminium: 500 V, 100  $\mu$ s and  $U_{\text{start}} = 76$  V, 60 mC). Precipitates are clearly visible when electrodes made of aluminium are used, some of them being marked by inserted arrows in a).

5 These particles precipitate onto the cells. But those particles are not visible if electrodes made of doped synthetic material are used so that precipitation of particles can be obviously avoided by the use of the container according to the invention. This fact has a positive effect on the survival rate of the cells and it is also beneficial for the further handling of the cells. Medical compatibility of the

10 electroporation products is hereby also enhanced so that, for example, the possible use of transfected primary cells for ex vivo gene therapy is affected particularly advantageous.

Figures 10 and 11 each show diagrams of a flow-cytometric analysis of cells

15 (Figure 10: HUVEC cells, Figure 11: CHO cells) which were incubated in differently treated solutions. The containers according to the invention were filled with simple buffer solutions, such as PBS, without cells and exposed to a high voltage pulse three times in a row (Aluminium: 500 V, 100  $\mu$ s and  $U_{\text{start}} = 115$  V, 100 mC; doped synthetic material: 1000 V, 100  $\mu$ s and  $U_{\text{start}} = 95$  V, 112

20 mC) in order to analyse the effects of possible cell-damaging components which could be released during an electric discharge from various electrodes made of doped synthetic material and from electrodes made of aluminium and which in addition to their direct effects reveal further effects on the cell culture just after the pulses. Subsequently, 100  $\mu$ l of the solutions pulsed by the various

25 electrodes were added to 400  $\mu$ l culture medium (EGM-2 BulletKit/Clonetics). HUVEC cells (values after 18 hours:  $5 \times 10^4$  cells, values after 96 hours:  $2.5 \times 10^4$  cells) and CHO cells (values after 20 hours:  $10^5$  cells, values after 72 hours:  $2 \times 10^4$  cells), respectively, were transferred into 24-well plates in these media. The number of dead cells and living cells, respectively, was flow-cytometrically

30 determined after various times of incubation at 37 °C and 5 % CO<sub>2</sub>. After detaching the cells using 1  $\mu$ g/ml trypsin in 1 mM Ethylenediaminetetraacetate in PBS and mixture of these cells with the culture supernatant, 0.25  $\mu$ l/ml propidiumjodide was added for determination of dead cells. For staining of living

cells, 0.2  $\mu$ M carboxyfluoresceindiacetate-succinimidylester (CFDA-SE) in PBS + 0.5 % bovine serum albumin were added and incubated for 2 minutes at room temperature before the flow-cytometric analysis. In order to determine the total number of cells in one probe a defined number of Flow-Count Fluorosphere Beads (Beckman Coulter) was added, which can be distinguished from the cells in the FACS. The counted number of cells could be extrapolated this way to the whole volume in one well. The results represented in figures 10 and 11 show that there is a slight advantage with the use of electrodes made of doped synthetic material if compared to electrodes made of aluminium. In particular, after 4 days the solutions pulsed using electrodes made of synthetic material are more beneficial in respect of survival and growth of CHO cells. With HUVEC cells a positive effect of the plastic electrodes used in comparison to conventional electrodes made of aluminium can be already observed after 24 hours. Thus, these results are an indication for a better compatibility of electrodes made of doped synthetic material in respect of the release of cell-damaging components, wherein the negative effects after the current flow have been investigated in this approach. Due to the avoidance of the release of toxic metal ions a better biological compatibility of the containers according to the invention is additionally achieved. Thus, these are primarily with respect to the further use of transfected cells, for example the use of transformed primary cells for ex vivo gene therapy, significantly more advantageous than conventional containers or cuvettes.

Figure 12 shows a perspective representation of one possible embodiment of a container according to the invention. The container 20 shown is generally formed like a conventional cuvette. The container is formed by an outer limit 21 which builds an inner chamber 22 which has the capacity for receiving an aqueous solution. For example, cells, derivatives of cells, subcellular particles and/or vesicles can be suspended in this aqueous solution. In addition to the aqueous solution or suspension, the container may also contain, for instance, adhering cells, derivatives of cells, subcellular particles and/or vesicles. Two parallel electrodes 25, 26 are disposed in two parallel and oppositely arranged sidewalls 23, 24 of the outer limit 21. Both electrodes 25, 26 are made of a

synthetic material which, according to the invention, is doped with at least one conductive substance. The dope may consist of, for instance, carbon fibers, graphite, soot, carbon nanotubes or an intrinsically conductive synthetic material, or a combination of one or several of these substances as well. The  
5 outer limit 21 consists of an transparent plastic material which is not electroconductive. Due to the injection-mouldability of all components the container 20 according to the invention can be produced using two-component injection moulding. In this case, at first the outer limit 21 was injection-moulded using an non-conductive plastic. The doped synthetic material being injection-  
10 mouldable as well was injection-moulded into recessed windows (which are not visible any more) through injection moulding channels 27, 28. Thus, a very simple and cost-effective production of the container 20 according to the invention is possible. Such container 20 being formed like a cuvette is primarily beneficial if it shall be used in a conventional electroporation device. However,  
15 depending on the kind of application, the container according to the invention comprises all possible embodiments that make sense anyway.

Figure 13 shows a perspective representation (b) of a possible embodiment of a container according to the invention as well as a longitudinal section (a) of the  
20 same. The container 30 shown is also formed like a cuvette. The container is formed by an outer limit 31 which builds an inner chamber 32 which acts for receiving an aqueous solution. Two parallel electrodes 33, 34 are disposed in two parallel and oppositely arranged sidewalls 35, 36 of the outer limit 31. Both electrodes 33, 34 consist of a synthetic material, for example polyamide 66 or  
25 polyamide 6, which is doped with at least one conductive substance according to the invention. In an advantageous embodiment of the invention the dope may be, for instance, a mixture of carbon fibers and graphite. The outer limit 31 consists of a transparent plastic material which is non-electroconductive. Because of the injection-mouldability of all components the container 30  
30 according to the invention can be produced using two-component injection moulding. Hence, at first the outer limit 31 can be injection-moulded of a non-electroconductive plastic material. The doped synthetic material which is also injection-mouldable may be subsequently injection-moulded in recessed

windows through injection moulding channels 37, 38. Thus, very simple and cost-effective production of the container 30 according to the invention is possible this way. An oblique part 39 is disposed in the lower half of the container 30, which enables the container 30 to be adapted to the geometry of the respective receiving element of the device used, i.e. an electroporator. Additionally, the distance between the electrodes 33, 34 may be varied by different designs of the oblique part 39 so that the forward resistance can be changed.

Figures 14 to 16 show diagrams of flow-cytometric analyses of transfected cells using cuvettes having electrodes according to the invention according to figure 13, which have a distance to each other of 1.5 mm. These containers are tested in direct comparison to cuvettes having electrodes made of aluminium with a distance between the electrodes of 2 mm. Due to the 25 % reduction of the distance between the electrodes the higher resistance of the material of the doped plastic was compensated in respect of aluminium in order to achieve effectively the same conductivity per cross-sectional surface. The experimental procedure with polymer cuvettes corresponds to that with aluminium, wherein an electroporator having spring contacts made of brass (Nucleofector™ I, amaxa GmbH, Cologne) was used. Cell specific Nucleofector™ kits (amaxa GmbH, Cologne) were always used as solutions for receiving the cells. The cuvettes according to the invention always comprise electrodes consisting of polyamide (PA6 or PA66) doped with about 38 – 42 % w/w carbon fibers and about 33 – 37 % w/w graphite (overall concentration of the dope: about 70 – 80 % w/w).

Figure 14 shows diagrams of a flow-cytometric analysis of HL-60 cells (human lymphoma cells) after electroporation using polymer electrodes (PA6) according to the invention compared to electrodes made of aluminium. 2 µg pEGFP-C1 DNA (Clontech) were added to each probe of 100 µl solution including 10<sup>6</sup> HL-60 cells (ATCC). Two voltage pulses (1000 V, 100 µs and  $U_{\text{start}} = 90 \text{ V}$ , 75 mC) were applied to various cuvettes containing these probes which were then immediately incubated in *Iscove's modified Dulbecco's medium* containing L-

glutamine and 20 % fetal calf serum (Gibco) in an incubator at 37 °C / 5 % CO<sub>2</sub>. After 24 hours the cells were harvested and propidiumjodide as well as 25.000 APC-marked beads (Becton Dickinson) were added to each probe. Determination of propidiumjodide-stained cells and transfected cells based on the absolute number of cells per probe in a flow-cytometer (FASCalibur, Becton Dickinson) was possible this way. It turned out herein that the transfection efficiency could be significantly increased and that the mortality rate could be slightly decreased by the use of cuvettes according to the invention in comparison to conventional cuvettes having electrodes made of aluminium.

10

Figure 15 shows diagrams of a flow-cytometric analysis of CD3<sup>+</sup> T-cells after electroporation using polymer electrodes (PA6) according to the invention in comparison to electrodes made of aluminium. 2 µg pH-2K<sup>K</sup> (mouse MHC I heavy chain) were added to each probe of 100 µl solution containing 5 x 10<sup>6</sup> freshly isolated PBMC. Two voltage pulses (1000 V, 100 µs and U<sub>start</sub> = 96 V, 56 mC) were applied without interruption to various cuvettes containing these probes which are then directly incubated in AIM-V medium containing 10 % fetal calf serum (Gibco) in an incubator at 37 °C / 5 % CO<sub>2</sub>. After 24 hours the cells were harvested and propidiumjodide as well as 25.000 APC-marked beads (Becton Dickinson) per probe were added. Additionally, the cells were stained using the fluorescein-isothiocyanate-stained anti-H-2K<sup>K</sup> antibody (Becton Dickinson) and an antibody against the human T-cell-specific CD3 antigen which is coupled to APC (Becton Dickinson). Determination of propidiumjodide-stained cells and transfected T-cells based on the absolute number of cells per probe in a flow-cytometer (FASCalibur, Becton Dickinson) was hereby possible. Approximately similar results could be achieved this way.

Figure 16 shows diagrams of a flow-cytometric analysis of human umbilical cord vein endothelial cells (HUVEC) after electroporation using polymer electrodes (PA6) according to the invention in comparison to electrodes made of aluminium. 2 µg pEGFP-C1 DNA (Clontech) was added to each probe of 100 µl solution containing 6.8 x 10<sup>5</sup> HUVEC cells. A voltage pulse (1000 V, 100 µs) was applied to various cuvettes containing these probes which were then

30

directly incubated in EGM-2 medium for endothelial cells (Clonetics) in an incubator at 37 °C / 5 % CO<sub>2</sub>. After 24 hours the cells were harvested and propidiumjodide as well as 25.000 APC-marked beads (Becton Dickinson) were added to each probe. Determination of propidiumjodide-stained cells and transfected cells based on the absolute number of cells per probe in a flow-cytometer (FASCalibur, Becton Dickinson) was possible this way. It turned out herein that with the use of cuvettes according to the invention instead of conventional cuvettes having electrodes made of aluminium, the transfection efficiency could be increased and the mortality rate could be decreased.

10

Figure 17 shows diagrams of a flow-cytometric analysis of HL-60 cells (human lymphoma cells) 24 and 96 hours after electroporation using polymer electrodes (PA66 and PA6) according to the invention in comparison to electrodes made of aluminium. Conditions and procedures generally correspond to those described in figure 14 with the exception that the cuvettes made of aluminium as well as the cuvettes according to the invention have a distance between the electrodes of 2 mm. The cuvettes used herein each further have electrodes made of polyamide doped with about 33 – 37 % w/w carbon fibers and about 23 – 27 % w/w graphite (overall concentration of the dope: about 55 – 65 % w/w). In order to compensate the higher resistance of the polymer electrodes different pulse parameters are used herein (Synthetic material: 1000 V, 100 µs and  $U_{\text{start}} = 102$  V, 75 mC and Aluminium: 800 V, 100 µs and  $U_{\text{start}} = 90$  V, 75 mC). Also in this approach, the transfection efficiency could be slightly increased and the mortality rate could be slightly decreased by the use of polymer electrodes according to the invention.

**List of abbreviations used:**

	A	Ampere
	C	Coulomb
5	CHO	Chinese hamster ovary
	cm	Centimeter
	DNA	Deoxyribonucleic acid
	Gew.-%	Percent by weight
	h	Hours
10	HL-60	Human lymphoma 60
	HUVEC	Human umbilical cord vein endothelial cells
	kV	Kilovolt
	mC	Millicoulomb
	mM	Millimolar
15	ms	Milliseconds
	PA	Polyamide
	PBMC	Peripheral blood mononuclear cells
	PBS	Phosphate-buffered saline
	pH	Negative logarithm of the hydrogen-ion concentration
20	PJ	Propidiumjodide
	RNA	Ribonucleic acid
	RPMI	Rosewell Park Memorial Institute
	$\mu$ g	Microgram
	$\mu$ l	Microliter
25	$\mu$ s	Microseconds
	U	Voltage
	$U_{\text{Anfang}}$	Voltage <sub>Start</sub>
	V	Volt
